Einarsson, Oddur Sigurðsson**

## Summary of available hydrological information in the Jökulsá á Dal and Jökulsá í Fljótsdal basins, Iceland

### 1. Introduction

The hydrology of the central part of Eastern Iceland is dominated by two main rivers, Jökulsá á Dal (also called Jökulsá á Brú) and Lagarfljót (see Fig. 1.), both originating in the large glacier Vatnajökull. The annual volume they carry to the ocean is very similar, but they are quite different in character, the former to a much larger extent of glacial origin. Jökulsá á Dal runs through a rather narrow valley formed by glaciers and has formed a narrow gorge most of the way to the lowlands, some places over 100 m deep. The slope is steep and gradual, with many rapids but no waterfalls. The sediment transport is extremely high supplying the seashore with new material, keeping the shoreline in balance.

The main tributary of Lagarfljót is Jökulsá í Fljótsdal, which is only about 1/5 of the discharge of Jökulsá á Dal at the glacier outlet. It runs through a mountain plateau below the glacier at elevation over 600 m called Eyjabakkar, where most of the coarse sediments fall out, and then down a narrow valley in a series of waterfalls. It then enters the lake Lögurinn at about 1/3 of the distance to the sea at an elevation around 20 m which makes it quite feasible for harnessing. Most of the other significant tributaries of Lagarfljót also enter the lake Lögurinn. The remaining fall to the sea is at the end of Lögurinn, where a small hydropower plant has been installed.

### 2. Hydrological surveying in the Jökulsá á Dal and Jökulsá í Fljótsdal basins

Systematic surveying of the water resources in the area started just before 1950, but gauges in Jökulsá í Fljótsdal and Jökulsá á Dal were started in 1962 and 1963, respectively. The long term mean of Jökulsá í Fljótsdal at gauge vhm109 is 28.6 m<sup>3</sup>/s and that of Jökulsá á Dal at gauge vhm110 is 144 m<sup>3</sup>/s. The average daily values for the two series are shown in Fig. 2, and the mean annual flows are shown in Fig. 3. The network of gauges was enlarged in the seventies and again in the late eighties and early nineties, reflecting an ever increased demand for high quality data for water resources assessments and hydropower plant designs. This has been supplemented by meteorological and glaciological measurements, as well as the development of a physically based hydrological model, that now covers both basins upstream of all proposed major power plant installations.

#### 2.1 The hydrometric network

The hydrometric network in the Jökulsá í Fljótsdal and Jökulsá á Dal river basins is summarized in the following table.

vhm no.	River; station	Starting date of recorder data	Elevation m a.s.l.	Area km <sup>2</sup>
<b>Basic network</b>				
34	Bessastaðaá, Fljótsdal; Hylvað	1970-07-23	25	111
109	Jökulsá í Fljótsdal; Hóll	1962-09-06	50	558
110	Jökulsá á Dal; Hjarðarhagi	1963-05-11	150	3312
146	Hrafnkela; Vaðbrekkufoss	1969-08-26	367	183
164	Jökulsá á Dal; Brú, Kálfseyrar	1970-12-16	341	2090
205	Kelduá, Fljótsdal; Kiðafellstunga	1977-05-10	100	262
206	Fellsá, Fljótsdal; Sturluflöt	1977-05-14	110	125
221	Jökulsá í Fljótsdal; Eyjabakkafoss	1981-07-22	630	296
<b>Supplementary network</b>				
165	*Laugará, Fljótsdal; Laugafell	1970-08-08	600	29
215	**Hölkna, Jökuldal; vestan Þrælaháls	1978-08-24	710	47.7
254	Kelduá, Fljótsdal; ofan Grjótár	1991-07-03	645	62.3
255	Ytri-Sauða, Hraunum; Sauðárvatnsós	1991-05-05	790	24.9

\* Discontinued from 1993-11-03 \*\* Discontinued from 1992-10-05.

The daily discharge records from selected gauges are presented in Appendix 1 and the bi-weekly discharge data of continuous water years in Appendix 2.

## 2.2 Hydrological characteristics

**2.2.1 Jökulsá á Dal basin** The Jökulsá á Dal river basin in East-central Iceland is one of the largest river basins in Iceland. The main contribution to its flow comes from the drainage of the largest outlet glacier of Vatnajökull, Brúarjökull, which covers some 1700 km<sup>2</sup> according to recent surveys. The glaciated drainage area of Jökulsá á Dal is 1410 km<sup>2</sup> (Björnsson and Pálsson 1991). The Brúarjökull is a surge-type glacier with recorded surges in the early 17th century and 18th century, in 1810, 1890, and in the fall of 1963. The water gauge at Hjarðarhagi, vhm110, was started in 1963, just prior to the most recent surge. Abnormal flows were recorded in the years after the surge, but the whole recorded period might be affected by the surge and, might, therefore, not be representative for flows during other periods (Snorrason, 1985). The effects of the surges have been studied (Guðmundsson et al. 1996), estimating a transient increase in discharge due to the advance which causes an increase in the ablation area, profile changes and breakup. This increase in discharge is estimated to be some 10-15% after the surge in 1963 lasting about 4-6 years. In addition a long term decline in discharge due to the reduced ablation area is associated with the surge and is estimated to be about 1% per decade as the glaciers recedes.

The runoff from the glacier is highly dependent on temperature causing large diurnal variation in the river flow, often amounting to some 50% in difference between the daily extremes. The seasonality of the flow is also pronounced with average daily low flows in winter around 10 m<sup>3</sup>/s and average daily summer flows often above 500 m<sup>3</sup>/s. There is also a large climatically induced variability between years with the lowest annual mean discharge of 100 m<sup>3</sup>/s, but the highest 186 m<sup>3</sup>/s. Long term variability is also present, both due to climatic variability as well as due to the periodic surges of the glacier.

The runoff from the non-glaciated areas which are about 1907 km<sup>2</sup> is characterized by a pronounced snowmelt peak in late spring and early summer, but outside the melting season, the runoff is rather low, especially during winter when it can go as far down as 2 l/s·km<sup>2</sup>. This characteristics is well shown in the records from Hrafnkela, vhm146, as well as in the difference between the gauge vhm164 and gauge vhm110 on Jökulsá á Dal, but the difference in drainage areas is 1211 km<sup>2</sup>.

Measurements of suspended sediment load have been carried out close to the location of both gauge vhm110 and vhm164 (Tómasson et al. 1996) since the beginning of discharge measurements. In recent times the samples have been taken from two bridges using a standardized sampler from the USGS (S49) and a winch. The sediment load of Jökulsá á Dal is extremely high with annual mean about 6-7 million tons/year with range from about 2-12 million tons/year, with the extreme of 18 million tons/year occurring right after the surge in 1963. From the sediment data it seems that the effects of the surge have died out over a period of about 15-20 years (Tómasson et al. 1996). No measurements of bedload have been carried out.

Floods are mainly of three types, spring floods due to snow melt, summer floods due to glacial melting and rainfall-snowmelt floods in fall and early winter. Historical information exists on extreme floods in Jökulsá á Dal in the past centuries. These are likely to be jökulhlaups, possibly associated with the surges of the glacier, but jökulhlaup associated with the surge in 1963 is the only jökulhlaup in the discharge record. Flood frequency analysis of the record is shown in Appendix 3.

**2.2.2 Jökulsá í Fljótssdal basin** The Jökulsá í Fljótssdal river basin in East-central Iceland is a medium sized glacial river draining an outlet glacier of Vatnajökull, called Eyjabakkajökull. The glaciated area is about 138 km<sup>2</sup> (Björnsson and Pálsson 1991) of the total about 555 km<sup>2</sup> at the gauge vhm109, close to the outlet of the river into lake Lögurinn. Eyjabakkajökull is a surge-type glacier, with its most recent surge in 1972. The period of surges is about 30-40 years but may be quite irregular as the glacier is composed of two different branches (Sigurðsson 1996a). Surges cause a long term variability in the riverflow, which has to be kept in mind when planning for the future.

The runoff characteristics are very similar to the one of Jökulsá á Dal, except the scale is much smaller. Proportionally larger areas are not covered with glaciers with higher specific runoff due to higher precipitation. Groundwater contributes very little to the flow, so the specific discharge is quite low during the winter season.

Measurements of sediment transport have been carried out along with the discharge measurements using similar sampling techniques as in Jökulsá á Dal. The total transport of suspended sediments is about 350 thousand tons/year, varying between less than 200 to over 700 thousand tons/year. Sediment transport is more confined to finer grain sizes due to the small slope of the river in front of the glacier terminus, where the coarser material settles. The effects of the surge of 1972 are clear in the sediment data and they seem to last about a decade (Tómasson et al. 1996).

Floods are of three types, spring floods due to snowmelt, jökulhlaup from the marginal lake Háöldulón (Sigurðsson 1966b) and rainfall-snowmelt floods during the fall and early winter. Drainage of Háöldulón can also take place as a gradual drainage, adding to the meltwater from the glacier. Flood frequency analysis for the record are shown in Appendix 4.

The Fljótsdalsvirkjun hydropower project is also based on diversions from adjacent watersheds, foremost from the watershed of Kelduá, to the south and east of Jökulsá í Fljótsdal. This river is measured in the lowlands at the gauge vhm205 which has been in operation since 1977. The mean discharge is 15.5 m<sup>3</sup>/s of which about 11 m<sup>3</sup>/s are included in the present project. Kelduá is characterized by high seasonality, with intense snowmelting in late spring and most of the summer, but very low flows during the wintertime. Extreme flooding can occur when heavy rainfall with associated snowmelt, takes place in late fall or early winter, when the ground is already frozen

### 2.3 Reliability of discharge and suspended sediment data

The extreme character of Jökulsá á Dal makes it a very difficult case to study and measure. The range of flows is very large, all of which are very important for hydropower development. The sediment transport is also extreme and very variable causing problems both with rating curves as well as with the operation of the water level gauges. Ice conditions prevail during the long winter causing considerable inaccuracies in the low flow data.

The discharge ratings are carried out with meters suspended from cableways. It is known from the literature that suspended meters can overestimate the discharge due to several reasons. Firstly, in very turbulent water a traditional propeller can overestimate the speed of water due to its inertia, secondly, the current meter is always aligned along the axis of maximum velocity, which is not always perpendicular to the measured cross-section. Thirdly, the measurements of the depth can give overestimation due to the drift of the weights. The experience at the Hydrological Service with ADCP (Acoustic Doppler Current Profiler) measurements on other large Icelandic rivers confirm that measurements with suspended meters during high flows can overestimate the discharge, even if heavy weights are used.

The rating curve at gauge vhm110 seem to be stable on a long term basis, but shifting between two states is observed, which is, without doubt, due to heavy sediment load. This shift occurs within the season so frequent measurements are needed to keep track of the shifts. Shifting is not observed at gauge vhm164.

Operation of water level gauges is troublesome due to the sediment transport, causing periods where the gauges are perturbed or clogged by the sediments. Long periods during winter are perturbed due to ice, which is not very important due to low base-flow.

The problems above apply only to a limited extent to the measurements of Jökulsá í Fljótsdal and are confined to the problems associated with the operation of water level gauges due to the sediment transport, causing periods where the gauges are perturbed or clogged by the sediments.

Discharge measurements in Kelduá are quite difficult due to high flows and difficult terrain causing an increase in the error margin of the flow values, especially for the extreme floods.

In both basins long periods during the winter are perturbed due to ice, which is not very important due to low base-flow.

Great difficulties are associated with measurements of suspended sediment load in Jökulsá á Dal due to the high levels of flow as well as sediment concentrations. Sediments of smaller grain sizes seem to be adequately measured, but measurements of coarser grain sizes are

biased downwards due to difficulties in the sampling procedures, therefore, underestimating the total suspended load. Measurements in Jökulsá í Fljótssdal do not pose the same problem. No measurements of bedload have been undertaken in any of the rivers.

#### 2.4 Other measurements

Glaciological measurements have been carried out in the two basins. Mapping of the glaciated areas was carried out on Eyjabakkajökull in 1981 (Björnsson 1988) and on Brúarjökull in 1988 (Björnsson and Pálsson 1991). Measurements of the terminus were started in 1972, and are still continued. Mass balance measurements have been carried out on Eyjabakkajökull since 1991 (Sigurðsson 1993), and on Brúarjökull since 1993 (Björnsson et al. 1995).

Meteorological measurements, in addition to the national network of the Icelandic Meteorological Service, have been carried out at some few locations in the basins, three of which are in operation. Of these, one is at Eyjabakkar, one in the eastern outskirts of the Jökulsá í Fljótssdal basin and one in the basin to the west of the Jökulsá á Dal basin.

#### 2.5 Hydrological modelling

Extensive hydrological modelling has been carried out in the two basins. The most recent one is a comprehensive physically based model of both basins, which is based on the Danish NAM-2 model developed at DTU and DHI and is similar in structure as the Swedish HBV model. The glacial routines have been developed further, as well as the groundwater model, which does not constitute an important part of the hydrological systems in these two basins. These efforts used all available hydrological, meteorological and glaciological data as well as data on the geology of the region. The results are published in reports from Vatnaskil Consulting (Vatnaskil 1993, 1995, 1996), in which the inflow series to all reservoirs and diversion points in the hydro power schemes of Jökulsá í Fljótssdal and Jökulsá á Dal were calculated.

### 3. Time series for the simulation of energy production

Hydrological time series for the simulation of energy production are supervised and approved by the *Streamflow Data Committee* (Rennslisgagnanefnd – REGN), a sub-committee of the National Power Company/National Energy Authority co-operative committee. A report on the series approved by REGN in the period 1984-94, up to and including its meeting no. 24, was published in 1995 (Einarsson 1995). The report documents series in the register number range R101 to R191, covering the water years 1950 to 1988, in some older cases (kept for comparison) 1950 to 1983. A part of the series kept in the REGN database is only for preliminary studies, and has not been approved by the committee for design studies.

After the publication of the report the following series have been added to the database, updated or replaced:

New no.	Replaces no.	Text	REGN meeting no.
R192	-	<b>Approved for design studies</b> Innrennsli í inntakslón Brúarvirkjunar	24
R193	-	Eyvindará við niðurfall í göng	24
R198	R188	Jökulsá á Dal, innrennsli í Hálslón	24
R141	R129	Ölfusá; Selfoss	25
R164	R118	Eyjabakkalón, innrennsli án Kelduár og Sauðárveitu	26
R165	R121	Hafursárskurður	26
R167	R124	Laugarárveita	26
R166	R125	Hafursárkvísl	26
R194	-	Fellsár-Sultarranaárveita	26
R195	-	Grjótá með Innri-Sauðá	26
R196	-	Kelduá ofan stíflu	26
R197	-	Ytri-Sauðárveita	26
R199	R116	Breytt rennsli í Blöndu undir 20 m <sup>3</sup> /s	27
R137	-	<b>Added for preliminary studies</b> Skaftá við Sveinstind. Vatnaskil	
R138	-	Innrennsli í Langasjó. Vatnaskil	
R160	-	Austari Jökulsá; Eyfirðingavað	
R161	-	Fossá; jökulrennsli	
R162	-	Geldingsá við sæluhúsið Grána	
R163	-	Veituleið til Stafnsvatna	

The series documented above cover the water years 1950 to 1993. In addition some of the series documented in the 1995 report have been extended to cover this period.

A new report for documenting the additions, replacements and updates since 1995 is now being planned.

## Appendix 1. Discharge data

In Appendix 1. tables of mean daily flows are shown for gauges vhm110 and 164 in Jökulsá á Dal, gauges vhm109 and vhm221 in Jökulsá í Fljótssdal and vhm205 in Kelduá í Fljótssdal.

The meaning of the terms in the table is as follows:

rennisskýrsla = discharge record

árið = year

einingar rennslis = units of discharge

meðaltal = mean (of the month)

hámark = highest instantaneous discharge (of the month)

lágmark = lowest instantaneous discharge (of the month)

dagur = day (of the month)

klst = hour (of the day)

dagur klst = day and hour of the extreme value (of the month)

\* = water level perturbed by ice; discharge estimated

á = missing record; discharge estimated

Q = actual discharge measurement during that day

N = noteworthy event

meðalrennslí ársins var = the annual mean discharge was

hámarksrennslí þess = the highest instantaneous discharge of the year

lágmarksrennslí þess = the lowest instantaneous discharge of the year

## Appendix 2. Bi-weekly discharge data

In Appendix 2 bi-weekly discharge data from continuous water years are shown for gauges vhm034 in Bessastaðaá river, vhm064 in Ölfusá river at Selfoss (a characteristic gauging station with natural inflow, west of the Thjórsá-Tungnaá basin), vhm097 in Thjórsá river at Sandafell (upstreams from Burfell, influenced by hydro power), vhm109 and 221 in Jökulsá í Fljótssdal, vhm110 and 164 in Jökulsá á Dal, vhm146 in Hrafnkela, vhm205 in Kelduá and vhm206 in Fellsá.

The data shown in the appendix are also given in separate files. It should be noted, that "natural inflow for a characteristic gauging station near Búrfell", which was requested, can not be given for the Þjórsá (= Thjórsá) river itself. The runoff at vhm097 Thjórsá; Sandafell is influenced by the actions of Man. The data given for vhm064 Ölfusá; Selfoss is only slightly influenced by Man. The basin is located to the west of the Thjórsá river basin and covers 5678 km<sup>2</sup>, less than the 6515 km<sup>2</sup> of Thjórsá at Sandafell.

The meaning of the terms in the table is as follows:

Rennslisröð = discharge series

Árið = year

Gl/2vikur = gigaliters per 2 weeks = million m<sup>3</sup> per 14 days

Gl/ári = gigaliters per year = million m<sup>3</sup> per year

Meðalrennsli = mean discharge

Fjöldi ára = number of years

Rennslisröð: Q34 Bessastaðaá, Fljótsdal; Hylvað

Jökulsá á Dal

Reiknuð og mæld hæstu flóð árána 1964-1993  
*Calculated and measured maximum floods*

# Vatnshæðarmælir 110

Vatnshæðarmælingar í Jökulsá á Dal hófust 1. september 1950, en þá var settur upp kvarði við Hjarðarhaga, en rekstur hans var mjög stopull, og verður kvarðatímabilið því ekki notað í þessari úrvinnslu. Síriti var svo settur upp þann 11. maí 1963 og hefur nákvæmni mælinga verið góð síðan, nema hvað sandur hefur oft truflað mælingar. Ísatruflanir hafa verið langvinnar, en tiltölulega auðvelt er að vinna úr þeim, þar sem rennslisbreytingar eru fremur hægar yfir vetrartímann. Hæsti álestur á síritann var 427 cm þann 10. október 1964.

## Flóð Jökulsár

Jökulsá á Dal er fyrst og fremst jökulá, þó hún hafi auðvitað nokkur dragaréinkenni. Vatnasvið Jöklu er 3323.0 m<sup>2</sup> en þar af eru 1434 m<sup>2</sup> jökull (eða 43%). Flóð Jökulsár á Dal eru ýmist leysingaflóð snemmsumars (maí - júní) eða jökulleysingaflóð síðsumars (júlí - ágúst), og eru þau álíka algeng. Haustflóð eru hins vegar mun sjaldgæfari í Jöklu, en í öðrum ám á Austurlandi. Brúarjökull þekur stóran hluta vatnasviðs árinnar og hleypur hann fram, en á árunum eftir framhlaup hans má búast við mun meiri jökulleysingu, en í venjulegu ári. Brúarjökull hljóp síðast frá 16. október 1963 og eitt ár fram. Mesta mælt rennsli Jökulsár á Dal við Hjarðarhaga er frá 10. október 1964, en dagana þar í kring urðu miklir hitar og haustrigningar á Austurlandi og varð flóðið fremur af þeim ástæðum, en að það tengdist beint framhlaupi Brúarjökuls. Hæsta rennslismæling á lykli er frá 18. júlí 1977 og reyndist rennslið vera 638 m<sup>3</sup>/s við vatnshæð 338 cm.

# Vatnshæðarmælir 109

Vatnshæðarmælingar í Jökulsá í Fljótsdal hófust 6. september 1962, en þá var settur upp síriti við Klyfahyl hjá Hóli. Annar síriti, vhm 234, er í Jökulsá í Fljótsdal við Eyjabakkafoss, en hann var settur upp 9. september 1985. Nákvæmni mælinga hefur verið ágæt. Ísatruflanir hafa verið langvinnar, en tiltölulega auðvelt er að vinna úr þeim, þar sem rennslisbreytingar eru afar hæggar yfir vetrartímann. Hæsti álestur á síritann var 412 cm þann 26. desember 1972, en þá varð þrepahlaup í ánni.

## Flóð Jökulsár

Jökulsá í Fljótsdal er blanda dragár og jökulár, en lindarþáttur árinna er mjög lítill eins og sést á langtímaferlinum á myndinni hér fyrir neðan. Af vatnasviði árinna þekur jökull 113 km<sup>2</sup> (eða 20%). Flóð Jökulsár í Fljótsdal eru þrenns konar, u.þ.b. þriðjungur þeirra er leysingaflóð að vori (maí - júní), annar þriðjungur eru jökulleysingaflóð á sumrin (júlí) og þriðjungur flóðanna eru haust- og vetrarflóð (október - desember), en þau eru einmitt mjög algeng í austfirskum ám. Þetta mynstur sést vel á ferlinum fyrir árið 1980, en þar eru einmitt þrjár toppar, sem skera sig úr á þessum tímabilum. Í Jökulsá í Fljótsdal koma einnig jökulhlaup úr Háöldulóni, en þau eru þó ekki alltaf stærri en stærstu leysingaflóð. Stærsta flóð í ánni var eins og áður segir þrepahlaup þann 26. desember 1972. Hæsta rennslismæling á lykli var gerð 13. júní 1989 og mældist rennslid 248 m<sup>3</sup>/s við vatnshæð 355 cm.
